June 13, 2017

ABSTRACT

I describe an architecture for linking perception and action in a robot. It consists of three "towers" of layered components. The "perception tower" contains rules that create increasingly abstract descriptions of the current environmental situation starting with the primitive predicates produced by the robot's sensory apparatus. These descriptions are deposited in a "model tower" which is continuously kept faithful to the current environmental situation by a "truth-maintenance" system. The predicates in the model tower, in turn, evoke appropriate action-producing programs in the "action tower." It is proposed that the actions be written as "teleo-reactive" programs---ones that react dynamically to changing situations in ways that lead inexorably toward their goals. Programs in the action tower are organized more-or-less hierarchically---bottoming out in programs that cause the robot to take primitive actions in its environment. The effects of the actions are sensed by the robot's sensory mechanism, completing a sense-model-act cycle that is quiescent only at those times when the robot's goal is perceived to be satisfied. I illustrate the operation of the architecture using a simple block-stacking task.

## I. Agent Architectures[1]

Can anything in general be said about intelligent agent architectures? Just as there are millions of species of animals, occupying millions of different niches, I expect that there will be many species of artificial agents---each a specialist for one of a countless number of tasks. The exact forms of their architectures will depend on their tasks and their environments. For example, some will work in time-stressed situations in which reactions to unpredictable and changing environmental states must be fast and unequivocal. Others will have the time and the knowledge to predict the effects of future courses of action so that more rational choices can be made. Even though there will probably never be a single, all-purpose agent architecture, there is one that I think might play a prominent role in many future systems. It can be viewed as an elaboration of

[1] Parts of this section are adapted from Chapter 25 of my book, *Artificial Intelligence: A New Synthesis*, San Francisco: Morgan Kaufmann, 1998.

the first two levels of the popular three-level architectures that have been prominent in robotics research.

## A. Three-Level Architectures

One of the first integrated intelligent agent systems was a collection of computer programs and hardware known as "Shakey the Robot" (Nilsson, 1984). Shakey's design was an early example of what has come to be called a *three-level architecture*. The levels correspond to different paths from sensory signals to motor commands.

At the lowest level of such architectures are actions that use a short and fast path from sensory signals to effectors. Important "reflexes" are handled by this pathway---such as "stop" when touch sensors detect a close object ahead. Servo control of motors for achieving set-point targets for shaft angles and so on are also handled by these low-level mechanisms.

The intermediate level combines the low level actions into more complex behaviors---ones whose realization depends on the situation (as sensed and modeled) at the time of execution. This level uses more abstract (or more "coarse") perceptual predicates and more complex actions than do the lower ones. Whereas reflex actions are typically evoked by primitive sensory signals, the coordination of intermediate-level actions requires more elaborate perceptual processing.

The third level usually involves systems that can generate plans consisting of a sequence of intermediate level programs.

The three-level architecture has been used in a variety of robot systems. As a typical example, see (Connell, 1992).

## B. The Triple-Tower Architecture

A generalization of the three-level architecture has been proposed by Albus and colleagues (Albus, 1991; Albus, McCain, & Lumia, 1989). They envision hierarchies or "towers" of perceptual, modeling, and action processing. We propose here a particular instantiation of their triple-tower architecture. The novel features of our proposal are:

1. The use of teleo-reactive programs in the action tower
2. The use of perceptual rules in the perception tower. These rules create increasingly abstract predicates from simpler ones
3. The use of a truth-maintenance system (TMS) to keep the predicates in the model tower continuously faithful to changes in the sensed environment

My version of this triple-tower architecture is illustrated in Figure 1. The operation of such a system would proceed as follows: Aspects of the environment that are relevant to the agent's roles are sensed and converted to primitive predicates and values. These are stored at the lowest level of the model tower. Their presence there may immediately evoke primitive actions at the bottom of the action tower. These actions, in turn, affect the environment, and some of these effects may be sensed---creating a loop in which the environment itself might play an important computational role.

The perception tower consists of rules that convert predicates stored in the model tower into more abstract predicates which are then deposited at higher levels in the model tower. These processes can continue until even the highest levels of the model tower are populated.

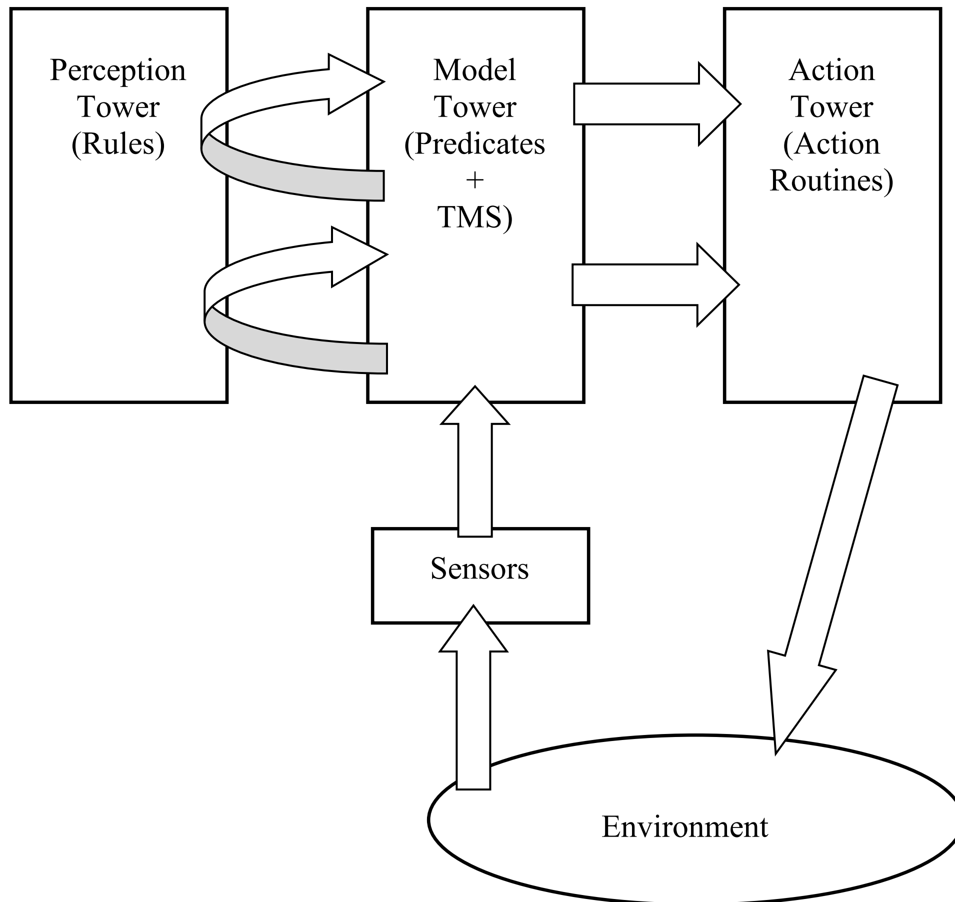

Fig. 1. A Triple-Tower Architecture

The action tower consists of a loose hierarchy of action routines that are triggered by the contents of the model tower. The lowest level action routines are simple reflexes---evoked by predicates corresponding to primitive percepts. More complex actions are evoked by more abstract predicates appropriate for those actions. High-level actions "call" other actions until the process bottoms out at the primitive actions that actually affect the environment.

We also allow for the possibility that the actions themselves might affect the model tower directly (in addition to the loop through the environment) by writing additional and/or altered content. With the ability both to read from and write in memory, the triple-tower structure is a perfectly general computational architecture.

In order to be responsive to ongoing environmental changes, we include a truth-maintenance system (TMS) as part of the model tower. Such a system should continuously delete predicates and values from the model tower that are no longer derivable (through the perceptual rules) from the then-present components of the model tower. We describe a specific example of such a triple-tower system in section III.

## II. Teleo-Reactive Programs

I propose that the actions be implemented as teleo-reactive (T-R) programs. For completeness, we give a brief overview of this formalism here.

A *teleo-reactive (T-R)* program is an agent control program that robustly directs the agent toward a goal in a manner that continuously takes into account changing perceptions of the environment. T-R programs were introduced in two papers by Nilsson (Nilsson 1992, Nilsson 1994). (See also the T-R web page at: www.robotics.stanford.edu/users/nilsson/trweb/tr.html.) In its simplest form, a T-R program consists of an ordered list of production rules:

$K_1 \rightarrow a_1$
. . .
$K_i \rightarrow a_i$
. . .
$K_m \rightarrow a_m$

The $K_i$ are conditions, which are evaluated with reference to a world model. The $a_i$ are actions on the world (or that change the model). In typical usage, the condition $K_1$ is a goal condition, which is what the program is designed to achieve, and the action $a_1$ is the null action.

A T-R program is interpreted in a manner roughly similar to the way in which ordered production systems are interpreted: the list of rules is scanned from the top for the first rule whose condition part is satisfied, and the corresponding action is then executed. A T-R program is usually designed so that for each rule $K_i \rightarrow a_i$, $K_i$ is the regression, through action $a_i$, of some particular condition higher in the list. That is, $K_i$ is the weakest condition such that the execution of action $a_i$ under ordinary circumstances will achieve some particular condition, say $K_j$, higher in the list (that is, with $j < i$ ). T-R programs designed in this way are said to have the *regression property*.

We assume that the set of conditions $K_i$ (for $i = 1, \ldots, m-1$) covers *most* of the situations that might arise in the course of achieving the goal $K_1$. In any case, we can set $K_m = T$ (or 1) as a default catch-all. If an action fails to achieve its expected condition, due to an execution error, noise, or the interference of some outside agent, the program will nevertheless typically continue working toward the goal. This robustness of execution is one of the advantages of T-R programs.

T-R programs differ substantively from conventional production systems, however, in that actions in T-R programs can be durative rather than discrete. A *durative* action is one that can continue indefinitely. For example, a mobile robot might be capable of executing the durative action move, which propels the robot ahead (say at constant speed). Such an action contrasts with a discrete one, such as move forward one meter. In a T-R program, a durative action continues only so long as its corresponding condition remains the highest true condition in the

list. When the highest true condition changes, the current executing action immediately changes correspondingly. Thus, unlike ordinary production systems, the conditions must be continuously evaluated; the action associated with the *currently* highest true condition is *always* the one being executed. An action terminates when its associated condition ceases to be the highest true condition.

The regression condition for T-R programs must therefore be rephrased for durative actions: For each rule $K_i \rightarrow a_i$, $K_i$ is the weakest condition such that continuous execution of the action $a_i$ (under ordinary circumstances) eventually achieves some particular condition, say $K_j$, with $j < i$ . (The fact that $K_i$ is the weakest such condition implies that, under ordinary circumstances, it remains true until $K_j$ is achieved.)

In a general T-R program, the conditions $K_i$ may have free variables that are bound when the T-R program is called to achieve a particular ground instance of $K_1$. These bindings are then applied to all the free variables in the other conditions and actions in the program. Actions in a T-R program may be primitive, they may be sets of actions executed simultaneously, or they may themselves be T-R programs. Thus, recursive T-R programs are possible. (See Nilsson 1992 for examples.)

When an action in a T-R program is itself a T-R program, it is important to emphasize that the usual computer science control structure does *not* apply. The conditions of *all* of the nested T-R programs in the hierarchy are *always* continuously being evaluated! The action associated with the highest true condition in the highest program in the stack of "called" programs is the one that is evoked. Thus, any program can always regain control from any of those that it causes to be called---essentially interrupting any durative action in progress. This responsiveness to the current perceived state of the environment is another one of the advantages of T-R programs.

Sometimes it is useful to represent a T-R program as a tree, called a T-R tree, as shown in Figure 2.

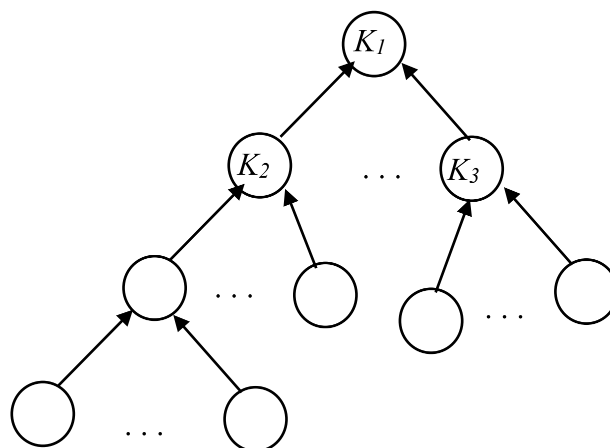

Fig. 2. A T-R Tree

Suppose two rules in a T-R program are $K_i \rightarrow a_i$ and $K_j \rightarrow a_j$ with $j < i$ and with $K_i$ the regression of $K_j$ through action $a_i$. Then we have nodes in the T-R tree corresponding to $K_i$ and $K_j$ and an arc labeled by $a_i$ directed from $K_i$ to $K_j$. That is, when $K_i$ is the shallowest true node in the tree, execution of its corresponding action, $a_i$, should achieve $K_j$. The root node is labeled with the goal condition and is called the *goal node*. When two or more nodes have the same parent, there are correspondingly two or more actions for achieving the parent's condition.

Continuous execution of a T-R tree would be achieved by a continuous computation of the shallowest true node and execution of its corresponding action. (Ties among equally shallow true nodes can be broken by some arbitrary but fixed tie-breaking rule.)

The "backward-from-the-goal" approach to writing T-R programs makes them relatively easy to write and understand, as experience has shown.

## III. A Triple-Tower T-R Agent Builds a Tower

As an illustrative example, I describe a triple-tower system for building a tower of blocks on a table. We assume the agent works in an environment of blocks and a table as shown in Figure 3.

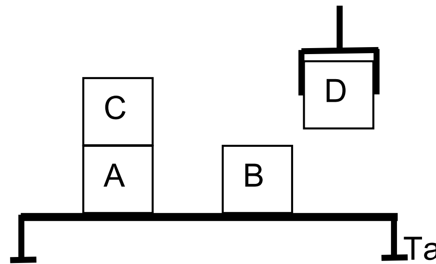

Fig. 3. Blocks on a Table

In this example, there are four blocks (A, B, C, and D), a table (Ta), and a hand that can move blocks from place to place. In the sketch, the hand is holding block D.

At the lowest level of the action tower are the action schemas <u>putdown(x,y)</u> and <u>pickup(x)</u>. The schema putdown(x,y) can be applied if the hand is holding block x and if y is either the table or a block with no other block on it. The result (if successful) is that block x is on y (that is, either directly on the table or on top of block y). The schema pickup(x) can be applied if no block is on block x and the hand is not already holding anything. The result is that the hand will be holding block x. We assume that these actions are "ballistic." They continue executing until they terminate (either successfully or in some type of failure).

The sensory system creates all of the instances of the predicates On(x,y) and Holding(x) that are satisfied by the environment. These are immediately placed at the bottom of the model tower. (These predicates have their obvious intended interpretations.) If applied to the environment of blocks and table shown above, the sensors would create and place in the model tower the following assertions: On(C,A), On(A, Ta), On(B, Ta), and Holding (D). These assertions

remain in the model tower only so long as direct sensory perception of the environment sustains them. (For example, if block C is moved, the assertion On(C,A) would be immediately deleted.)

The goal of our block-stacking agent is to make a tower of blocks with all of the blocks in the tower ordered from top to bottom as specified by a user. The user specifies the order, from top to bottom, by a list, such as (A, B, C). The complete system for this example is shown in Figure 4.

The perception tower is composed of a number of rules that are invoked in the forward direction to create new predicates---more abstract than the primitive ones, which are created directly by the sensors. These rules are invoked by predicates that are already in the model. The results are inserted in the model. For example, the rule

$\neg(\exists x)\mathrm{On}(x,y) \wedge \neg\mathrm{Holding}(y) \supset \mathrm{Clear}(y)$

can be used to assert Clear(C) in the model tower because (by reference to the model) there is no assertion of the form On(x,C) and there is no assertion Holding(C). (We assume "negation as failure.") Similarly, we can assert Clear(B).

The rule

$\mathrm{On}(x,\mathrm{Ta}) \supset \mathrm{Ordered}(\mathrm{list}(x))$

can be used to assert Ordered((A)) and Ordered((B)) in the model because both On(A,Ta) and On(B, Ta) are in the model already. (The Lisp construct "list(x)" creates a list whose single element is the argument x. Note our use of other Lisp notation throughout the example.) Using the various rules in the perception tower, more abstract predicates come to populate the model tower. The model tower is used to evaluate predicates as needed by the T-R programs in the action tower. Keep in mind however, that all of these model assertions are subject to a truth-maintenance system that continuously updates them as the (sensed) environment changes.

A user can specify a tower to be built by calling the top-level T-R program, maketower(x), with x instantiated to whatever tower s/he desires. For example, s/he might call maketower((A,B,C)). Calling this program invokes other T-R programs in the action tower. Their invocation ultimately results in the execution of primitive actions whose primitive effects are sensed and recorded in the model tower---leading to the insertion and retraction of other predicates and the evocation of other actions. The reader is invited to trace through a successful execution. Note that the evocation of T-R programs is not strictly hierarchical. Lower level programs can call those at a higher level. Note also that the top-level program, maketower, is recursive. Remember that called programs are allowed to continue only so long as the relevant condition in the program that called them remains in the model tower---throughout the entire stack of T-R programs invoked at any time.)

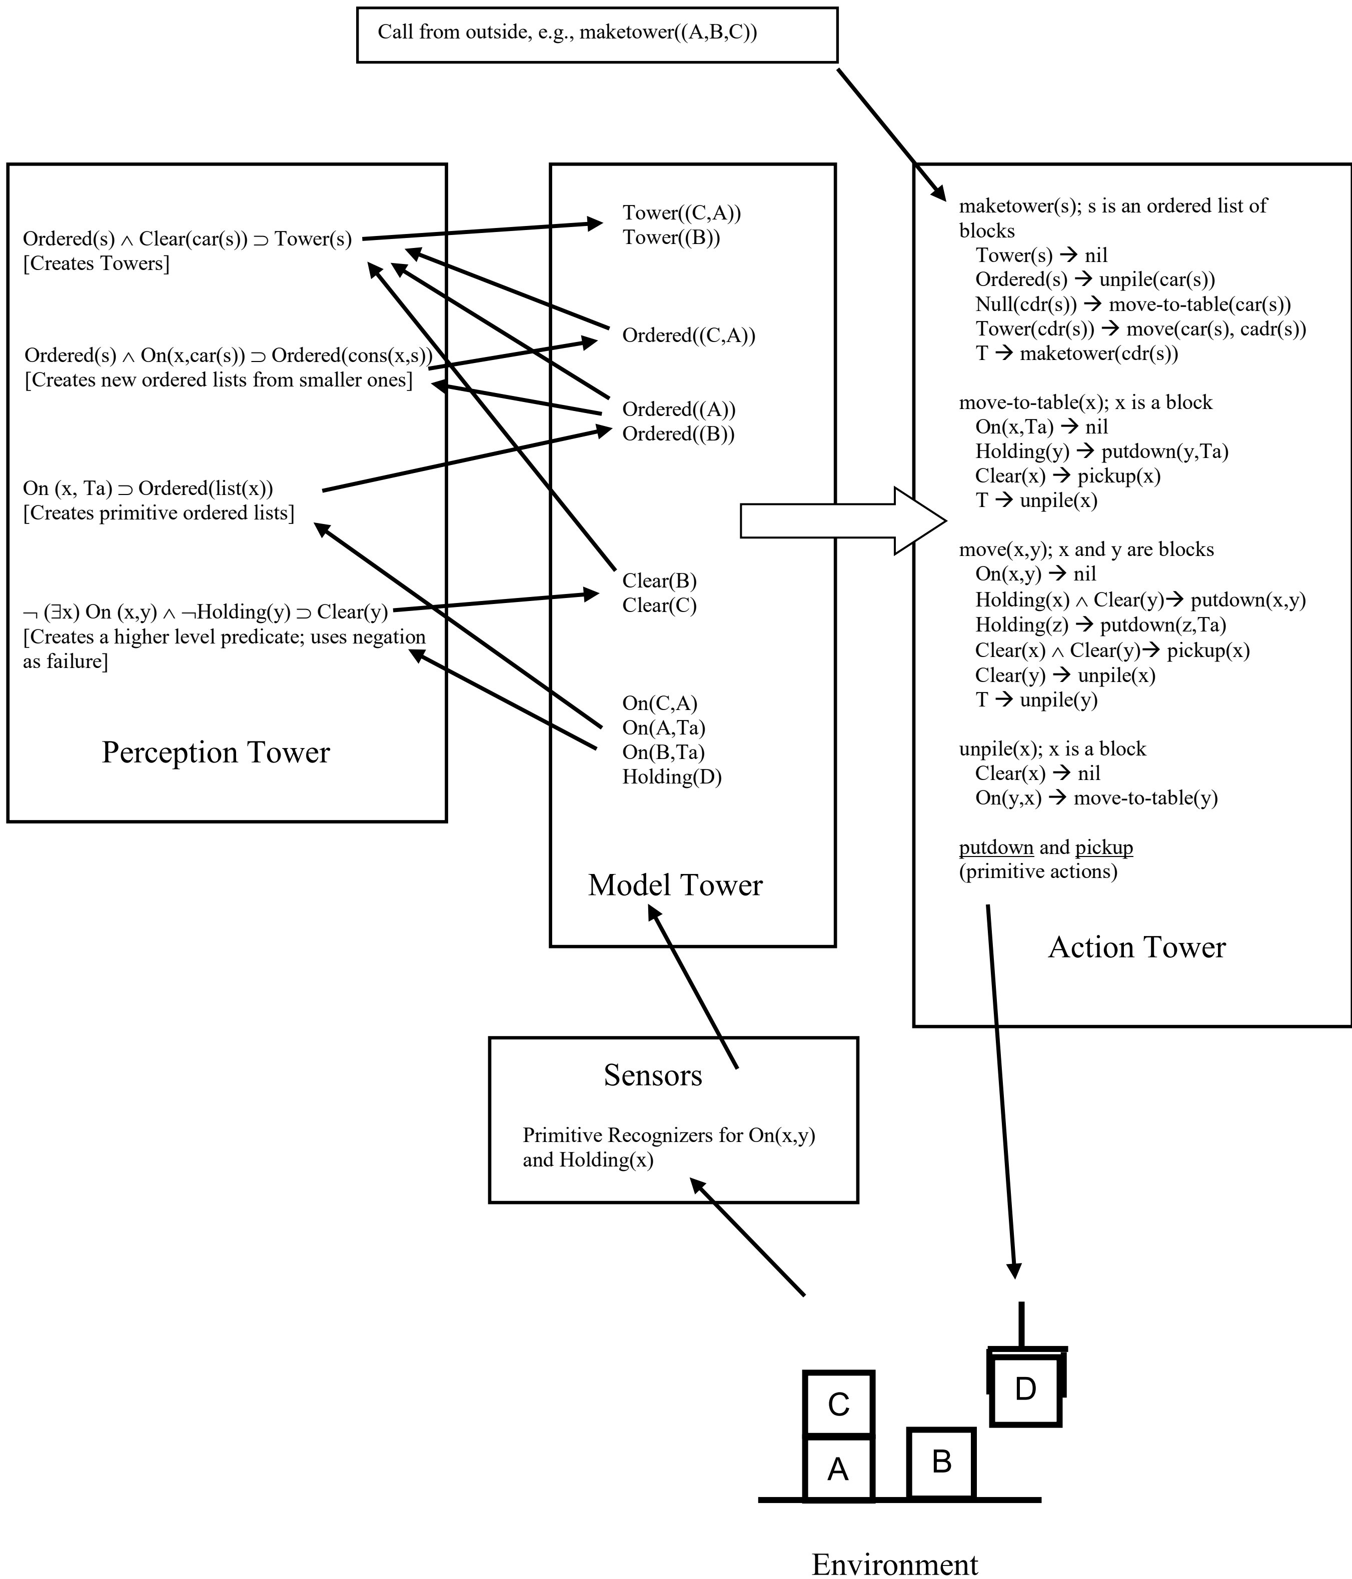

Fig. 4. Triple-Tower Architecture for Building a Tower

The architecture just described is capable of building any single tower without the need for search. The complexity is polynomial in the size of the tower. [Compare with a similarly efficient scheme for tower building proposed by (Chapman, 1989). The "blocks world" is NP-hard only for building multiple towers (Gupta & Nau, 1992).]

A Java applet[2] implementing this triple-tower, T-R system is available on the web at: www.robotics.stanford.edu/users/nilsson/trweb/TRTower/TRTower.html.

## IV. The Vision

Our example shows that it is relatively straightforward to design a triple-tower T-R system for simple, demonstration-type tasks. The challenge is to see whether or not such systems can be designed for the many real-world tasks that we want robots and agents to perform. As we have seen, there are three major components to be synthesized, namely, abstractions of sensed data, rules for creating these abstractions, and hierarchies of T-R programs. The abstractions, rules, and programs are all interdependent, which can make synthesis of complex programs difficult.

In addition to the manual methods of synthesis (such as was employed to develop the block-stacking system), we can also employ automatic planning and learning techniques. By themselves, planning and learning methods are probably not sufficient for the synthesis of large and effective robot control programs *ex nihilo*. I believe that efforts by human programmers at various stages of the process will continue to be important---initially to produce a preliminary program and later to improve or correct programs already modified by automatic planning and learning techniques. I envision that four methods, namely programming, teaching, reinforcement learning, and planning might be interspersed in arbitrary orders. It will be important therefore for the language(s) in which programs are constructed and modified to be languages in which programs are easy for humans to write and understand and ones that are compatible with machine learning and planning methods. These requirements most likely rule out, for example, C code (it would be hard to learn) and neural networks (they would be hard for humans to understand and modify), however useful these formalisms might be in other applications. T-R programs, on the other hand, are easy for humans to write and modify, and there has already been some progress on their synthesis by automatic planning and learning methods.

Benson's TRAIL system produces T-R programs via a planning system that employs STRIPS-type rules learned by inductive logic programming (IPL) methods (Benson 1996). As regards other varieties of learning, we might distinguish two types, namely teaching and reinforcement learning. *Teaching* involves someone showing the robot what is required by "driving" it through various tasks. This experience produces a training set of conditions and corresponding actions, which can then be used by supervised learning methods to clone the behavior of the teacher in the form of T-R programs. *Reinforcement learning* involves on-the-job trials guided by rewards given by a human user or teacher, and/or by the environment itself. Preliminary work on the use of teaching and reinforcement learning to produce T-R programs is described in (Nilsson 2000).

---

[2] Running the applet requires the Java 2 Runtime Environment (JRE), version 1.3 or above. Visiting the applet's website should result in your being asked if you want this JRE downloaded to your computer. You can check the version number of your JRE by typing under the shell prompt: java-version. JRE v1.3 can be downloaded from Sun; it is available for the platforms: Microsoft Windows, Linux (x86), and Solaris (SPARC/x86).

There is also other research that might be relevant to the hierarchical aspects of learning triple-tower systems. Pfleger has investigated on-line techniques for detecting frequently occurring, hierarchically related sub-strings within data streams (Pfleger, 2001). Drescher has proposed methods for building concepts based on Piagetian cognitive development (Drescher, 1991). Stone has developed a layered learning architecture for robotic soccer players (Stone, 2000). And Dietterich proposes methods for hierarchical reinforcement learning (Dietterich 1998).

I think the triple-tower architecture provides an interesting setting for an attack on the problem of synthesizing mid-level control systems for robots and other agents.
