Abstract: Brazil has great potential for biomass production. There are several processes to convert biomass into energy, among these is the biological conversion of organic carbon into methane. This work aimed to estimate the production of biogas in a poultry slaughterhouse in Matelandia state of Paraná, Brazil, by the IPCC methodology. The poultry slaughterhouse slaughter 140,000 poultries a day and generates a wastewater FLOW OF 3,360 m³.d⁻¹. Electricity consumption by the industry plant is about 3,600 MWh.month⁻¹. The treatment system used in industry is the physical and biological process, and the pre-treatment consists of a static sieve and a flotation equipment, followed by stabilization ponds. Two anaerobic ponds were covered with a geomembrane of High Density Polyethylene and was installed a gas meter to measure the flow rate of biogas production. The biogas generation potential estimated can reduce 3.89% of the electricity consumed.

Keywords: Bioenergy, Anaerobic digestion, Wastewater, IPCC.

1. Introduction

In the past decades, the consumption of meat chicken in many countries has been on the increase. As a result of the growing poultry industry, poultry slaughterhouses are producing increasing amounts of by-products and wastes.

The production and export of chicken meat perform an important role in the Brazilian economy. According to the ABEF - Brazilian Association of Chicken Producers and Exporters, in 2009, Brazil was among the international reach first place in the export sector and third in world production of chicken meat, behind the United States and China. The southern region of Brazil has an important role in the achievement of these data, because it focuses on the major poultry production and consequently the processing industries of chicken meat, accounting for approximately 75% of national production. The State of Paraná is the largest producer of chicken meat from Brazil, exporting in the year 2009 a total of 954,653 5 tonnes of chicken meat.

The interest in recovering the biogas generated by stations for sewage treatment, urban solid waste landfills, residue of sugar cane, by the biodigestion of the vinasse, livestock manure anaerobic digestion and poultry slaughterhouse wastewater associated with its energetic use and managing these residues, have been discussed in Brazil.

Anaerobic digestion is a biological process that occurs in the absence of oxygen, where organic matter is degraded and transformed in gaseous mixture called biogas. The biogas composition is highly variable depending on various aspects like the characteristics of biomass and environmental conditions offered. The average composition of biogas has the following values: CH₄ (50-75%), CO₂ (25-50%), N₂ (0-10%), H₂ (0-1%), H₂S (0-3) and O₂ (0-2).
Wastewater as well as its sludge components can produce CH$_4$ if it degrades anaerobically. The extent of CH$_4$ production depends primarily on the quantity of degradable organic material in the wastewater, the temperature, and the type of treatment system. With increases in temperature, the rate of CH$_4$ production increases. Below 15°C, significant CH$_4$ production is unlikely because methanogens are not active and the lagoon will serve principally as a sedimentation tank. However, when the temperature rises above 15°C, CH$_4$ production is likely to resume.$^5$

This paper objectives to evaluate the potential for methane production in a poultry slaughterhouse by the IPCC methodology, and the potential for generating electricity from the energy use of the methane produced in anaerobic digestion process.

2. Methodology

2.1. Water consumption and wastewater characteristics in poultry slaughterhouses

The according to the sanitary requirements related to processing and industrialization of meat, the demand for water in this activity is high, it can be considered an average consumption of 25 a 50 L,$^6$ 25 L$^7,8$ ou 17 L a 20 L by poultry slaughtered$^9$.

It is recognized that minimising water consumption and contamination has wide reaching environmental benefits. Increasing the volume of water used automatically affects the volume of waste water which has to be treated at either an on-site or a municipal waste water treatment plant. Water makes contact with a carcass or any animal by-product, whether during production or cleaning, contaminants such as fats or blood are entrained and these increase the burden on the waste water treatment plant. In many cases the water used is hot, so energy will have been used to heat it. Also the fats can melt in hot water and then become more difficult to separate from the water.$^5$

The references of wastewater characteristics available in the literature described in Table 1, have several values due different water consumption by poultry slaughtered, operational practices, size of the industry, collecting the effluent at different points, among others.

2.2. Characterization of the case study

The industrial plant slaughter 140,000 poultry.d$^{-1}$, generating a flow of wastewater from 3.360 m$^3$.d$^{-1}$, resulting in 24 L.poultry slaughtered$^1$.

The wastewater treatment system use in the industry is compound by categories pre-treatment, primary and secondary through the physical and biological processes. Pre-treatment consists of a static sieve to remove solids, the primary treatment in flotation
equipment for the physical process for removal of oils and greases and secondary treatment is the arrangement of two biodigesters in parallel, an aerated pond with aeration sub-surface endowed with aerators and 6 also air vents and a facultative pond.

The main physical and chemical characteristics of wastewater are COD average Biodigester influent: 3,390 ± 1,275 mg L⁻¹ and COD average Biodigester effluent: 1,205 ± 300 mg L⁻¹.

Measurements of water consumption were made by water meters installed at seven points of the production process, which resulted in consumption values by sector.

The industry in question has a demand of 3,360 m³.d⁻¹ accounting for water consumption in all productive sectors, from receipt of the birds, washing trucks, bleeding, scalding, evisceration, cooling room, cuts, water sanitation cleaning equipment and industrial plant, boiler until the dispatch of meat.

Electricity consumption from the poultry slaughterhouse is 3,600 MWh.month⁻¹, resulting in approximately 1.07 kWh.poultry slaughtered¹.

2.3. Estimate of the methane potential production

The principal factor in determining the CH₄ generation potential of wastewater is the amount of degradable organic material in the wastewater. Common parameters used to measure the organic component of the wastewater are the Biochemical Oxygen Demand (BOD) and Chemical Oxygen Demand (COD). Under the same conditions, wastewater with higher COD, or BOD concentrations will generally yield more CH₄ than wastewater with lower COD (or BOD) concentrations⁵.

Considering the IPCC Guidelines for National Greenhouse Gas Inventories – Chapter 6: Wastewater Treatment and Discharge, was used following the methodology to account the methane production potential in poultry slaughterhouse in Matelandia, Paraná, Brazil.

Emissions are a function of the amount of organic waste generated and an emission factor that characterises the extent to which this waste generates CH₄.

Three tier methods for CH₄ from this category are summarised below:

The Tier 1 method applies default values for the emission factor and activity parameters. This method is considered good practice for countries with limited data.

The Tier 2 method follows the same method as Tier 1 but allows for incorporation of a country specific emission factor and country specific activity data. For example, a specific emission factor for a prominent treatment system based on field measurements could be incorporated under this method. The amount of sludge removed for incineration, landfills, and agricultural land should be taken into consideration.

For a country with good data and advanced methodologies, a country specific method could be applied as a Tier 3 method. A more advanced country-specific method could be based on plant-specific data from large wastewater treatment facilities.

This paper follow the Tier 2 method.

Step 1: Estimate total organically degradable carbon in wastewater (TOW) for industrial
sector i.

\[ TOW_i = P_i \times W_i \times COD_i \] (1)

Where:
- \( TOW_i \) = total organically degradable material in wastewater for industry \( i \), kg COD/yr
- \( i \) = industrial sector
- \( P_i \) = total industrial product for industrial sector \( i \), t/yr
- \( W_i \) = wastewater generated, m³/t product
- \( COD_i \) = chemical oxygen demand (industrial degradable organic component in wastewater) kg.COD.m⁻³

Step 2: Select the pathway and systems according to country activity data. Use Equation 2 to obtain emission factor. For each industrial sector estimate the emission factor using maximum methane producing capacity and the average industry-specific methane correction factor.

\[ EF_j = Bo \times MCF_j \] (2)

Where:
- \( EF_j \) = emission factor for each treatment/discharge pathway or system, kgCH₄/kg.COD
- \( j \) = each treatment/discharge pathway or system
- \( Bo \) = maximum CH₄ producing capacity, kg.CH₄/kg.COD
- \( MCF_j \) = methane correction factor

Good practice is to use country and industry sector specific data that may be available from government authorities, industrial organizations, or industrial experts. However, most inventory compilers will find detailed industry sector-specific data unavailable or incomplete. If no country-specific data are available, it is good practice to use the IPCC COD-default factor for Bo (0.25 kg CH₄/kg.COD).

2.4. Electricity Generation Potential

The estimate electricity generation potential by the biogas produced was calculated following this equation:

\[ P_{el} = \frac{PCI_{CH₄} \times M_{CH₄} \times \eta_{el}}{kWh \times 1000 \times 100} \]

Onde:
- \( P_{el} \): Electricity generation potential MWh.year⁻¹
- \( PCI_{CH₄} \): Methane Calorific value: 50 MJ.kg⁻¹
- \( M_{CH₄} \): Unit conversion factor: 0,2778
- \( \eta_{el} \): Electricity Generation System Efficiency: %

3. Results

The methane generation potential is 515,963 kgCH₄.year⁻¹, equivalent 1.414 kgCH₄.d⁻¹. Considering a electric generation efficiency of 30% for the motor, the methane generation can produce 1,681 MWh.year⁻¹, or 4.61 MWh.d⁻¹.
4. Conclusion
The biogas produced by the anaerobic digestion process can reduce 3.89% of the electric energy consumption at poultry slaughterhouse.
